ABSTRACT

The uptake of four radionuclides (Sr-85, Ru-106, Cs-137, and Ce-144) was measured for four plants (wheat, tomatoes, corn and potatoes) grown in four different soil types (sandy loam, sandy clay loam, silty clay and clay). Plants were grown in large soil containers that allowed most of the root system to develop under normal field conditions. Plant uptake contamination factors (a_{SU}) were calculated for each sample harvested. Comparisons of the uptake for various plant part-soil-radionuclide combinations at crop maturity showed that the a_{SU} values for Sr-85 were the largest in all instances, usually by an order of magnitude. The a_{SU} values for the edible portion of each plant were lowest in every case, and usually the leafy portions of the plants had the largest a_{SU} value.

Additional experiments included measurements of changes in radionuclide uptake caused by available calcium levels, growing crops in large fields, and contaminant form and solubility.

PREFACE

This report summarizes research conducted by Stanford Research Institute under Contract No. N0028867C2036. The work was performed under the sponsorship of the Office of Civil Defense through the Technical Management Office of the U.S. Naval Radiological Defense Laboratory.

The authors wish to thank the U.S. Naval Radiological Defense Laboratory for the use of their Camp Parks Test Station. We particularly wish to thank Melvin J. Nuckolls and James L. Thomas of that laboratory for their assistance and cooperation.

We also thank Mr. Robert Schultz for his efforts and cooperation in growing our field crops at the University of California Kearney Horticultural Field Station.

In addition, we wish to express our appreciation for the work of Charles Bubics of the Pleasanton Nursery who assisted in all experimental phases of the work and was responsible for the maintenance of the crops used in the experiment.

SUMMARY

This report describes the results of experiments conducted for the purposes of evaluating the uptake of selected fission product radio-nuclides through their root systems, and for evaluating the dependence of the contamination factors on such parameters as plant type, soil type, plant age, soil nutrients, and fallout solubility. It was also necessary to correlate the measured plant uptake contamination factors with soil characteristics for subsequent application in mathematical root uptake contamination models.

The approach taken followed earlier work in which plants were grown in large containers under conditions designed to reproduce, as closely as possible, the growth of food crops under actual field conditions. In addition, during the current work, a limited number of field tests were conducted to test the hypothesis that the large containers used provided a realistic simulation of an actual environment. Primary consideration was given to the study of radiostrontium with crops also grown in Cs-137, Ru-106, and Ce-144 soil containers which were available from previous experiments. The farmland plots were contaminated only with radio-strontium. Test soils included sand, loam, and clay soils from previous work and two additional soils representing widely distributed California agricultural soils. The crops studied were wheat, tomatoes, corn, and potatoes.

Sampling started as soon as the plants sprouted and continued at frequent intervals depending on growth characteristics of the plant. Plant uptake contamination factors (a_{SO}) were calculated for each of the

samples harvested. Comparisons of the uptake for various plant part-soil-radionuclide combinations at crop maturity showed that the a_{SU} values for Sr-85 were the largest in all instances, usually by an order of magnitude. The a_{SU} values for Cs-137, Ru-106, and Ce-144 showed no consistent pattern and were distributed randomly high and low among the plant part-soil combinations. The a_{SU} values for the edible portion of each plant were lowest in every case, and usually the leafy portion of the plants had the largest a_{SU} value. These general observations support and extend the results of previous experiments.

Only limited data were available for evaluating the effects of available calcium on radionuclide uptake but, taken with the results of previous work, supported the postulated decrease in uptake in a manner approximately inversely proportional to the exchangeable calcium concentration in the soil. These results again emphasized the generally lower uptake values observed in the work as compared to literature values. The lower values in these experiments have been attributed to the growing of crops in large containers, as opposed to values based on literature data which are reported for experiments using small pot containers. The large soil containers allowed the plant root systems to develop in a manner closer to field conditions.

To test this assumption further some field studies were conducted in which crops were grown on all test plots at two different field locations. The data were not extensive enough to confirm the validity of the large container approach but were in sufficiently good agreement to support the continuing application of the large container data to estimations of postattack food contamination levels. As part of the field studies, a limited number of additional experiments were conducted to compare measured a_{SU} values for various methods of mixing the contaminant with the soil and also to compare the results obtained by applying the contaminant in normal particle form and also as a solution. In all cases no significant differences were found.

By far the largest changes in a_{SU} values were produced when the availability of the radionuclides for uptake was reduced by thermal pretreatment of the fallout simulant. The results verified the previous reductions in a_{SU} values for wheat by as much as a factor of 10. In the present work the observations were extended to include the three additional crops of tomatoes, corn, and potatoes and similar reductions in a_{SU} values were found.

INTRODUCTION

Evaluation of the biological consequences from ingesting radionuclides in foods depends first on a knowledge of the paths by which radionuclides enter the food chains and second on the availability of information about the uptake or assimilation processes. The two major paths of entry into food chains of plants are: (1) foliar contamination by deposited fallout particles followed by foliar adsorption of soluble radionuclides, and (2) uptake of radioelements by the plants through root assimilation. In both paths, the biological availability of a given radioelement for uptake depends on its solubility in the aqueous media that is in contact with the plant tissues since transfer across plant membranes generally requires an ionic form.

The dependence of nuclide solubility on the conditions of fallout formation and the methods for relating plant contamination to gross fallout deposition levels are discussed in Reference 1; these fallout properties and the related solubility behavior of all the fission product radioelements are described in terms of a set of contour ratios that are defined as the ratio of the surface density of some property of fallout to the standard intensity in roentgens per hour at one hour. Use of the standard intensity as derived from fallout models--or from postattack monitoring data--would serve as input data for a systematic method of estimating or predicting the relative amount of each radioelement in the fallout that various food crops would assimilate.

The radiological hazard to humans and animals from food contaminated by fallout from a set of hypothetical nuclear attacks on the continental United States was evaluated in a study conducted for the Office of Civil

Defense, Department of Defense,² using a series of computational models.^{3,4,5,6} The conclusions of the study were derived from analyses of available data on direct plant-foliar contamination, the initial contamination of drinking water sources, and the uptake by plants through their root systems.

Analyses of available plant uptake data⁷ indicated that additional experiments were needed to provide root uptake contamination factors for many plants, fission product radionuclides, soil types, and plant age combinations. Experimental verification of these plant uptake contamination factors is needed to provide an improved technical basis for establishing requirements for long term postattack countermeasures and for planning future postattack research program needs on the internal contamination problem and on the cycling of radionuclides in the food chain.

Background

During the past two years, research efforts⁸ were initiated to obtain the required plant uptake data. This research included the establishment of experimental facilities at the U.S. Naval Radiological Defense Laboratory Test Station (Camp Parks, Pleasanton, California) for growing plants in soil containing radionuclides and conducting full scale experiments to obtain plant uptake contamination factors of five radionuclides (Sr-85,^a Zr-95, Ru-106, Cs-137, and Ce-144) for seven crops (wheat, beans, tomatoes, lettuce, carrots, clover, and radishes) grown in three different soil types (sand, loam, and clay).

Plants were grown in large soil containers that allowed most of the root system to develop as it would under normal field conditions. Sampling started as soon as the plants sprouted and continued at frequent

^a Used as a tracer for fission product Sr-90.

intervals depending upon growth characteristics of the plant. Plant uptake contamination factors were calculated for each of the harvested samples.

Comparisons of the contamination factors for the various combinations of plant parts, soils, and radionuclides showed that, at crop maturity, the contamination factors for radiostrontium were usually an order of magnitude larger than for the other radionuclides tested. The values of the contamination factors for Cs-137, Ru-106, Zr-95 and Ce-144 were approximately equal with the highest and lowest values distributed randomly among the tested plant part and soil combinations. For all radionuclides, values of the contamination factors for the edible portion of each plant were lowest.

Analysis and correlation of the measured plant uptake contamination factors revealed that the concentration of radionuclides in plant parts and the concentration of available calcium in the test soils were related as predicted by a mathematical model which took the form

$$a_{SU} = a_{SU}^0 \left[Ca^{++} \right]^{-m} \text{ where } a_{SU}^0 \text{ and } m \text{ are empirical constants and } \left[Ca^{++} \right]$$

is a measure of the calcium concentration in the soil. Constants for the equation were derived for each plant part-soil-radionuclide combination, and the derived a_{SU} values were found to be in disagreement with those reported in Reference 7. It was noted, however, that the literature values reported in Reference 7 were computed on the basis of experiments in which plants had been grown in small containers where the root systems were contained in contaminated soil throughout the growth period. This situation was avoided in the current series of experiments by growing plants in large soil containers, with a "plow layer" of contaminated soil, which allowed the root system to develop beyond this layer. As a result

of this more realistic simulation, the derived a_{SU} values were lower, some by a factor of 10, than those measured for plants grown in small containers.

The analysis of the data indicated that further experiments should be conducted to measure additional plant-soil-radionuclide combinations and to supplement the experiments using a soil with a high calcium content. The extension of the work to field experiments involving the actual contamination of farmland, followed by normal cultivation practices, was also recommended for the purpose of verifying the uptake factors obtained in the large size containers.

Theory

Major factors that influence the uptake of radionuclides by plants through their root systems are:

1. Physicochemical properties of the ions of the radioelement
2. Plant species
3. Soil type and physical-chemical characteristics
4. Soil management practices

Assimilation of nutrients or inorganic ions by roots of plants usually involves soluble, exchangeable ions in the native soil. When foreign ions, for example, from a mineral fertilizer are introduced into the soil, they compete with and replace the native soil ions on available exchange sites in the soil. In some reactions with the soil, the new ions become non-exchangeable and, to the extent that these reactions occur in a soil, some portion of the new ion becomes unavailable for uptake. Thus, in the case of fallout particles, it would be expected that the types of interactions between soluble radionuclides and soil constituents would determine the availability of the radionuclides for uptake from the soil.

Soil management practices include the addition of organic matter, mineral fertilizers, and amendments (such as lime) to the soil, plus various cultivation techniques. These practices influence the chemical composition of the plant.

Since the availability of a given radioelement for uptake from soil is generally related to the concentration of the exchangeable portion of the radioelement in soil, the foliage or plant part contamination factor is conveniently defined in terms of its concentration in soil. Thus, the plant part soil uptake contour ratio, UN_1^0 , as given in Reference 5, is

$$UN_1^0 = N_1^0 (1 - a_{L L} w_L) a_{SU} w_p / \rho D \frac{\text{atoms per plant part}}{\text{square foot of soil area}} \quad (1)$$

in which

N_1^0 is the number of soluble atoms per square foot of "open field" area of the i th nuclide corrected to detonation time,

a_{SU} is the plant uptake contamination factor, in atoms of i th nuclide in plant part (atoms per gram of dry plant part) divided by the atoms of i th nuclide in soil (atoms per gram of soil),

w_p is the surface density of the plant part, in grams of dry plant part per square foot of soil area,

$a_{L L}$ is the foliage contamination factor in atoms per gram of dry foliage divided by the number of atoms per square foot of soil area,

w_L is the foliage surface density in grams of dry foliage per square foot of soil area,

ρ is the bulk density of the soil, in grams per cubic foot,

and

D is the depth of plowing in feet.

The term $(1 - a_{L L} w_L)$ is the fraction of N_1^0 that is deposited on the soil; on bare soil, w_L is zero. The surface deposit density, $(1 - a_{L L} w_L) N_1^0$

divided by D gives the effective concentration of the soluble radionuclide per gram of soil. The fraction of a radionuclide taken up by a plant part is given by $a_{SU} w_p / \rho D$.

The plant uptake contamination factor, a_{SU} , depends on the various chemical equilibrium and exchange processes among the soil minerals, roots, and plant tissues. These experiments were concerned with the measurements of a_{SU} .

Objectives

The objectives of this study were to:

1. Measure experimentally the uptake of fission product radionuclides by plants through their root systems and to evaluate the dependence of the contamination factors on such parameters as plant type, soil type, plant age, soil nutrients, and fallout solubility.
2. Correlate the measured plant uptake contamination factors with radionuclide soil characteristics for application in mathematical root uptake contamination models.

Approach

The physical properties of particle size and deposited mass level for the simulant were determined from the fallout models developed by Miller.¹ These models provide a means of estimating fallout particle size and deposited mass levels as functions of weapon yield, dose rate, and downwind distance. Clark has presented these relationships in a form readily applicable for use in the design of realistic experiments using fallout simulants.⁹ For the present experiment, a deposited mass level of 24 grams per square foot and a particle size range of 88 to 177 microns were chosen. These values have been calculated for a fallout

deposit that would be expected 90 miles downwind from a 14 MT land surface detonation. The experimental procedures were designed to reproduce, as closely as possible, the growth of food crops under actual field conditions. In this experiment, as in previous work, the selected crops were planted in cubic yard soil containers. Crops were also planted in plots of contaminated farmland and grown under actual field conditions to test the hypothesis that the large containers provide realistic simulation of an actual field environment.

In the present experiment, primary consideration was given to the study of radiostrontium, the importance of which was demonstrated in the previous work, where a_{SV} values were usually an order of magnitude greater than those obtained for other radionuclides. Crops were also grown in the Cs-137, Ru-106, and Ce-144 soil containers which were available from the previous experiment. The farmland plots were contaminated only with radiostrontium.

Additional tests were conducted with thermally treated synthetic fallout since previous work had indicated that such treatment resulted in a reduced uptake of radiostrontium.

The three soils (sand, loam, and clay) were used again, along with two widely distributed agricultural soils in California. The two new soils, a Hanford sandy clay loam and a Yolo loam, were obtained from University of California field test stations. A few tests were conducted with soil from the Camp Parks area. Test soils with a range of calcium concentrations were prepared by adding gypsum to Hanford sandy clay loam. Crops studied in this experiment included wheat and tomatoes which were included in the previous experiment and two additional crops (corn and potatoes which are important food in the U.S. diet).

Table 1 outlines the crops, radionuclides, and soils studied. Details of the experimental approach and experimental procedures are further described in the following section.

 Camp Parks clay

* Plant part underlined indicates the primary part from the standpoint of human ingestion.

EXPERIMENTAL PROCEDURES

Through the auspices of the sponsoring agency, the Office of Civil Defense, the U.S. Naval Radiological Defense Laboratory (USNRDL) made available its test facilities located at Camp Parks, near Pleasanton, California. These facilities include hot-cells for handling curie amounts of radioisotopes, and large land areas with controlled access. In addition, the University of California made available a plot of farmland at their Kearney Horticultural Field Station, Reedley, California, for the growing of crops under open field conditions.

Growing Facility

A 100 x 100-foot paved test area, enclosed with an eight-foot high solid board fence served as a growing facility for the root-uptake experiment. Electrical power, water, and lights were conveniently located within the area. A covered work space for plant handling and soil processing filled the west side. Laboratory bench tops and a sink that drained to a large stainless steel holding tank were provided for processing harvested plants. A large oven for drying the plants was located in the work area.

Climatological measurements in the plant growing facility during the experiment included: (1) a continuous recording of the temperature and humidity with a U.S. Weather Bureau recording hydrothermograph exposed in a standard instrument shelter, and (2) a measure of precipitation with a standard U.S. Weather Bureau rain and snow gauge.

The recorded rainfall, maximum and minimum temperatures, and relative humidity over the time span of the experiment are summarized in Table 2.

Table 2

Redwood boxes, three feet on a side (soil surface area of 7.3 square feet) served as soil containers. Each box contained about one cubic yard of soil and the three-foot depth allowed the root system of most of the crops to develop in a manner similar to that expected under normal field conditions (at least during the seedlings' early growth stages). The arrangement of the boxes within the test facility is shown by Figure 1. Four factors determined the box arrangement: (1) boxes containing the same radionuclide were kept together to prevent cross contamination among different radionuclides; (2) similar crops within each row were placed adjacent to each other to facilitate planting and maintenance; (3) a 10-foot aisle between rows was provided for moving boxes with a fork lift; and (4) boxes were placed to minimize the effect of the shadow line of fences.

Polyethylene sheeting lined the inside of each box, except the bottom, to prevent evaporation through the seams in the sides of the box. A 4-inch layer of pea gravel in the bottom of the boxes facilitated drainage of excess irrigation water. Galvanized trays were positioned beneath each box to catch this water.

Field Plots

Extension of the experiments to growing crops in contaminated plots of farmland was carried out at two locations, Camp Parks and the University of California Kearney Horticultural Field Station, Reedley, California. At both locations, the land areas were enclosed by a 6-foot high exclusion fence.

The layout of the farmland area utilized at the Kearney Horticultural Field Station is given in Figure 2. Four 25' x 45' plots were constructed. Each plot was surrounded by a one foot high berm and a 15' x 25' area inside the berm was contaminated with the Sr-85 fallout simulant. At Camp Parks, a single 25' x 45' plot was utilized.

FIGURE 2 Sr-85 UPTAKE EXPERIMENT AT KEARNY HORTICULTURAL FIELD STATION, REEDLEY, CALIFORNIA

Soils

Soils selected for this study included the three test soils used in the previous plant uptake experiment⁸ and two additional soils representative of agricultural soils found in California. The two additional soils, a Hanford sandy clay loam and a Yolo loam, were obtained from University of California field test stations.

Sufficient stocks of the previously used soils were on hand at Camp Parks, and sixty tons of each of the new soils were provided by random shoveling the top 8 inches from the surface at each site and trucking it to the plant growing facility.

Each redwood box was filled with a selected soil to within 10 inches of the top. Four hundred and fifty pounds of the same soil was then barreled and reserved for later addition as an 8-inch plow layer of radioactive soil. The soil was tamped and moistened during the filling process to approximate its original field compactness.

Table 3 lists a description of the test soils and where each was obtained. Samples of each soil were sent to commercial soil testing laboratories for chemical analysis. Tables 4 and 5 list the results of these analyses.

Radionuclides

Strontium-90, because of its relatively long half-life of 28 years and its appreciable yield in the fission process, accounts for a considerable fraction of the total activity of fission products that are several years old. Strontium and calcium are divalent alkaline earth elements, and since calcium is essential to plant life, strontium competes with it for entry into the root system of plants. Not all calcium in soil is available for uptake through the root system because some natural calcium compounds in soil are insoluble and are not available as plant food until

they have been converted into soluble compounds. For this reason, it is desirable to relate the uptake of Sr-90 to the exchangeable calcium content of soils. It was assumed that plants cannot discriminate among the different isotopes of a chemical element. For this reason, and because of the desire to analyze the radioactivity in the plant samples by means of counting gamma activity, the isotope strontium-85 was used as a tracer for the radiostrontium to take advantage of counting the gamma activity of its 0.51 mev photon.

Cesium-137 has a radioactive half-life of 30 years and is of particular interest in fallout that is more than a year old because cesium is the principal constituent whose radioactive decay is accompanied by the emission of gamma rays. The chemical properties of cesium resemble those of potassium, another essential element in the nutrition of plants.

Fallout Simulant

Fallout particles from a land surface nuclear explosion consist of fused, sintered, and unaltered grains of soil minerals and other materials present at the point of detonation. Analysis of fallout particles from surface and near-surface detonations at weapons tests in both Eniwetok Proving Ground and the Nevada Test Site have shown that radioactive elements are located within the interior of the fused and sintered particles and deposited on the surface of all three types of particles.¹

The fallout formation process consists of two distinct periods. In the first period, the condensation of volatile radioelements occurs by deposition onto and diffusion into large molten (soil) particles and by agglomeration of smaller particles. The radioelements thus condensed become fused within the volumes of the molten particles when they cool and solidify. In the second period, the remaining volatile radioelements condense onto the surface of relatively cool or solid particles. The fraction of a radioelement that condenses during the second period of

formation is partially soluble and therefore potentially available for biological assimilation in plants. Radionuclides in worldwide fallout are known to be quite soluble; but only limited data exist on nuclide solubility of local fallout. Because of the general lack of reliable solubility data for local fallout, approximate methods were developed for estimating the potential solubility of the various radioelements carried by fallout particles. Studies to measure solubility and thus improve the input data for the solubility model are in progress.^{10,11,12}

The basic fallout simulant employed in this study consisted of radionuclides adsorbed on the surface of sized mineral particles. The adsorption process simulates the second period of the fallout formation process, making the adsorbed radionuclides potentially available for uptake. The radionuclides were adsorbed on the particles from carrier solutions containing stable atoms of the major fission product elements. Sufficient activity was added to ensure measurable counting rates in the harvested plant samples.

Albite, a widely distributed variety of feldspar, was used as the mineral matrix on which the strontium was adsorbed. The albite was crushed, pulverized, and sieved to obtain particles in the 88-175 micron diameter size range. Magnetic separation removed the ferrous material that was introduced during the crushing and pulverizing operation.

The Sr-85 for this experiment was produced by neutron irradiation. A total of 0.073 grams of enriched $\text{Sr}(\text{NO}_3)_2$ was purchased from Oak Ridge National Laboratory. The enrichment in Sr-84 was given as 83.3 percent of total strontium and on this basis it was estimated that the compound contained 1.77×10^{20} atoms of Sr-84. The compound was sealed in a quartz capsule and delivered to the General Electric Company, Vallecitos, California, for insertion in the GETR.* The capsule was irradiated in a

* General Electric Test Reactor.

neutron flux of approximately 4×10^{14} neutrons $\text{cm}^{-2} \cdot \text{sec}^{-1}$ for one cycle (one month).

The quartz vial containing the strontium nitrate was opened in the Camp Parks hot cell, dissolved in approximately 250 ml. of IN HNO_3 . An aliquot of the solution was assayed in the 4-pi ionization chamber and gave 2.10 mc/ml at 1000, 24 May 1967, or a total activity of approximately 525 mc Sr^{88} . Decayed to the time of reactor shut-down, this would indicate a total production of approximately 590 mc.

On May 25, 1967, the solution was taken to dryness and then taken up in 200 ml. of IN HCl . An assay of the solution gave 2.49 mc/ml at 1015 May 25, 1967, or a total of 499 mc. This solution was used for the preparation of a number of batches of synthetic fallout as described in the following paragraphs:

1. A portion of sized albite of about 2-5 kilograms was poured into a twin shell blender* which had been modified to include a copper tube spray nozzle which could be inserted through a hole drilled in one of the bearing supports.
2. As the blender rotated, a measured aliquot of carrier solution containing one of the nuclides of interest was transferred by air pressure through plastic tubing connected to the spray nozzle. The transfer lines were then rinsed with two aliquots of wash solution which were also sprayed into the blender.
3. Following thorough mixing of the liquid and mineral, a mild stream of warm air was introduced via the spray nozzle. The drying operation was assisted by the use of an infra-red heat lamp directed onto the surfaces of the rotating blender.

* Manufactured by Patterson & Kelley Co., East Stroudsburg, Pennsylvania.

4. After drying, 175-gram portions of the fallout simulant were poured into tared plastic containers. Between portions, a small aliquot of about 1-2 grams was placed in test tubes for later assay in a gamma ionization chamber.
5. The 175-gram lots were finally placed in a lead shielded container and transferred to the plant growing facility for mixing with the test soils.

One exception to the above procedure consisted of a relatively large batch of simulant which was prepared for the field plantings. This batch was prepared in a small concrete mixer which had been modified to include a cover through which the spray nozzle could be inserted. Approximately 32,000 grams (70.5 pounds) of albite were placed in the mixer and sprayed with Sr^{88} solution containing approximately 133 mc total activity. Two 100 ml. rinses were added and the mixture was tumbled until dry. A summary of the strontium tagged synthetic fallout data is presented in Table 6 along with the re-assay values for the previously used Ce-144, Ru-106, and Cs-137. The indicated values are decay corrected to the date of planting. Table 6 also includes assay data for three batches of synthetic fallout which had been heated to successively higher temperatures of 880, 1027, and 1071°C.

Soil Contamination

Soluble radionuclides from fallout contaminated soil are made available for uptake by (1) surface penetration with rain water or natural erosion processes, and (2) mechanical mixing into the soil by cultivation processes. It has been demonstrated^{13, 14, 15} that fallout particles deposited on open land areas are not susceptible to any large degree of redistribution by wind and rain and, after several years of weathering, still are retained within the top 1/4 to 1/2 inch of surface soil. The

Table 6

SUMMARY OF SYNTHETIC FALLOUT AND CONTAMINATED SOIL ACTIVITY

* T1, T2, and T3 indicate three temperature levels (880°, 1027°, and 1071°C) to which synthetic fallout was heated before mixing in soil.

soluble radioelements that leach from deposited fallout particles from either local or world-wide fallout, penetrate no more than 2 to 3 inches, even after eight years.¹⁸ Mixing the fallout with the soil to the depth of cultivation is, therefore, the principal method by which radioelements from fallout would penetrate into the seed-bed.

As plowing is probably the most extensive form of cultivation, many experiments have been directed to a study of the effectiveness of various depths of plowing in reducing surface fallout levels. In most cases, little advantage was found for plowing to a depth greater than 6 to 8 inches. To simulate the mixing of fallout particles to this depth of cultivation, the fallout simulants prepared in this experiment were thoroughly mixed with the top eight-inch layer of soil in each container. This was accomplished by placing 450 pounds of a particular soil type into a modified concrete mixer and adding 175 grams of tagged particles (synthetic fallout). Twenty minutes of mixing was adequate to thoroughly blend the tagged particles with the soil. The contaminated soil was then dumped into hoppers and transferred to a partially filled soil box where it was tamped into place to simulate an 8-inch depth of cultivation or plow-layer. Table 7 summarizes the fallout simulant batches and lists the number of contaminated growing boxes which were prepared.

In addition to the naturally occurring exchangeable calcium in the native soils, higher calcium concentrations were obtained by adding an agricultural gypsum* to the plow-layer (450 pounds) of Hanford sandy clay loam. The measured exchangeable calcium content of 3.45 meq per 100 grams of native soil was adjusted with gypsum by the additions noted in Table 8. The measured amount of agricultural gypsum for each addition was added to the soil along with fallout simulant in the rotating concrete mixer to ensure blending.

* Chemical form; calcium sulfate dihydrate, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$.

* Molecular weight of $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ = 172.17 grams, 97% purity.

A commercial fertilizer (Loamite) with a fertilizer ratio* of 2-6-2 was also added to the rotating concrete mixer. Since the recommended rate of application for the crops and soils used was 750 pounds per acre, 0.125 pound was added for the 7.3 square foot soil surface in each box.

Contamination of the farmland plots at the Kearney Field Station and at Camp Parks was accomplished by dispersing the fallout simulant from a handpulled garden fertilizer spreader. An aluminum angle frame was used as guide rails for the spreader, and careful positioning of the frame for each swath ensured a uniform and complete deposition. A total of 14,130 grams (31.1 pounds) of the material was spread on the Camp Parks farm area over a measured plot of 20 x 22 foot dimensions. The spreading took place on June 19, 1967, and ion chamber assay of counting aliquots gave 4.07 $\mu\text{c}/\text{gram}$ as of 0930 on June 19, 1967. Planting took place on the same date. A small amount (130 grams) of fallout remained after spreading so that the final deposition was 14,000 grams per (20 x 22) square feet times 4.07 $\mu\text{c}/\text{gram}$ to give 129.5 μc per square foot at a surface density of 31.8 grams per square foot.

The remaining dry fallout (weighed at 41.9 pounds or 19,022.6 grams) was dispersed over two plots at the U.C. Agricultural Station, Reedley, California, on June 27, 1967. The contaminated areas were 15'7" x 25' and 15'8" x 25' for a total of 781.25 square feet. Following dispersal, the residual fallout was weighed at 286.5 grams to give a total surface density of 23.98 grams per square foot. The assay was 4.07 $\mu\text{c}/\text{gram}$ as of 0930 on June 19, 1967.

* Fertilizer ratio is the proportion of the three principal nutrients in a mixed fertilizer; namely, phosphoric acid, nitrogen, and potash.

Crops

The crops studied in this experiment included two analyzed in the previous plant uptake experiment, wheat and tomatoes and two additional crops, corn and potatoes, which are also important food crops in the U.S. diet. Table 9 presents the botanical classification of the selected crops. The variety with respect to human diet includes a grain crop (wheat), a vegetable crop (tomato), a root crop (potato), and a grain and animal fodder crop (corn). At planting time, the top 2-inch layer of soil in each box was cultivated to provide suitable conditions for seed germination. The surface of the clay and loam soils which became abnormally hard and cracked when dry, was treated with an organic humus which was mixed into the top 2-inch layer of soil. Table 10 presents a planting summary listing all boxes planted, the radionuclide, and the date of planting.

* Boxes 108 and 115 contain soils contaminated with Cs-137.

Planting Procedure

The procedures for planting in the soil containers were chosen to allow the crops to grow as near actual field conditions as possible. Depth of planting, row spacing, crop density, and growth characteristics were determined after consulting with personnel from the College of Agriculture, University of California, Davis, California. Table 11 lists these factors for each of the crops planted.

Certified seeds of each crop were obtained to ensure trueness to type and to eliminate the possibility of seed-borne diseases. The Agricultural Experiment Station, University of California College of Agriculture, Davis, California, provided certified seeds of field crops (wheat and potatoes), and Ferry-Morse Seed Company, Mountain View, California, provided certified seeds of vegetable crops (tomatoes and corn). Sufficient quantities of each type of seed were obtained to allow successive plantings.

Table 11

PLANTING PROCEDURES IN SOIL CONTAINERS

<u>Crop</u>	<u>Depth of Planting (inches)</u>	<u>Number of Rows</u>	<u>Row Spacing (inches)</u>	<u>Thinned Plant Spacing (inches)</u>
Wheat	1-1/2	5	6	2
Tomatoes	1	2	12	4 plants/box
Potatoes	4	2	12	4 plants/box
Corn	2	2	12	12

A commercial nursery* provided the routine care required to ensure proper growth of the plants. This included watering, cultivating, fertilizing, and spraying for insect control as required.

Table 12 summarizes the crops planted at the two farmland locations. As indicated earlier, wheat was planted at both locations. Additional crops consisted of tomatoes at the Kearney Field Station and corn at Camp Parks. The wheat at both locations was hand broadcast and then raked into the surface layer of soil, and the tomatoes were transplanted at the Kearney Field station from seed flats of the Hanford sandy clay loam. The tomatoes were approximately two weeks old at the time they were transplanted.

Plant Sampling and Analysis

The soil boxes and field plots were assigned a number to identify with a crop-soil-radionuclide combination. A summary of the various combinations is presented in Table 13. With the assigned number as the prefix, successive samples from each area were numbered serially by adding two digits. Thus, sample 104 indicated the fourth sample from box number 1; sample 11518 indicated the 18th sample from box number 115.

Plant sampling started soon after the plants emerged from the ground and continued at frequent intervals thereafter (at least seven days between samples), depending on the growth characteristics of the plant. The frequent sampling facilitated the thinning process that is usually required. When the plants were thinned to the desired spacings, sampling intervals were lengthened to ensure sufficient samples at harvest time. Sampling procedures depended on the type and age of the plant. Table 14 summarizes the plant parts sampled at each stage of growth. In the early stages, the whole plant was sampled; however, when the root system

SUMMARY OF PLANT PARTS SAMPLED

<u>Plant</u>	<u>Plant Age (days)</u>	<u>Sampled Parts</u>
Corn	21 - 47	Shoot
	29 - 70	Stalk, leaves
	58 - 84	Stalk, leaves, tassel
	76 - 119	Stalk, leaves, tassel, silk, husk, ear
Potatoes	99 - 126	Stem, leaves, tuber (meat, peel), root
Tomatoes	27 - 34	Shoot
	42 - 54	Vine
	41 - 70	Stem, leaves
	70 - 89	Stem, leaves, flower
	99 - 195	Stem, leaves, fruit (meat, peel), root
Wheat	21 - 50	Shoot
	41 - 97	Stalk, leaves, head
	90 - 110	Stalk, leaves, head, grain, chaff

developed, the plant stalk was cut off above soil level to avoid disturbing the soil around adjacent plants. Only at the final harvest were the roots sampled for analysis.

Generally, in the sampling process, washing of the plants was minimized to avoid the possible loss of soluble radionuclides. Yet, care was taken to ensure the removal of all soil particles from the sampled plants. Consequently, the root crop plant (potatoes) was carefully processed to remove soil particles. A portion of each potato crop was peeled after washing and the peel and meat portions analyzed separately.

After harvesting and washing, plants were separated into parts as indicated in Table 13. Plant parts were put into separate plastic containers and placed in a large forced air drying oven for a minimum of 24 hours at 70°C,* or longer if required, to yield a constant weight. The crops that contained large quantities of water, such as tomatoes and potatoes, were dehydrated before being dried to a constant weight.

Plant Radioactivity Assay

Dry plant samples were transferred from the large drying oven in the growing facility to a smaller oven in a nearby field laboratory. Samples were then removed from the oven and weighed on a semi-micro balance (Mettler Model B-6). After weighing, a portion, or all of the plant sample was placed into "Nalgene" test tubes for gamma activity measurement in a scintillation counter. The Nalgene tubes are made of a plain polypropylene, 32 x 172 mm with a 100 ml capacity. To ensure good counting efficiency in the well crystal, the dry plant material was compressed to a volume which generally ranged between 10 and 30 cubic centimeters. Care was taken not to exceed the latter volume which corresponded to the top of the crystal well. Approximately 20 grams of dry plant material could be counted in this manner.

* Association of Official Agricultural Chemists, 12.2 p. 116, 1945.

The scintillation counter consisted of a 3 x 3-inch NaI crystal with a 1-3/8 x 2-1/4-inch deep well mounted on an EMI type 95768 3-inch multiplier phototube whose output was fed directly into a Systron model 1091-3 scaler. The scaler gate was controlled by a Nuclear Dual Timer. A John Fluke Model 412A high-voltage power supply provided dynode string voltage for the multiplier phototube. Shielding consisted of a lead cylinder 3 inches thick, 9 inches I.D. and 22 inches high. A 2-inch thick lead cover moved back and forth to permit access to the well crystal.

The well crystal was calibrated by observing the count rate of small aliquots of radionuclide solution which contained a known amount of radioactivity. The counting aliquots were transferred to the "Nalgene" tubes from 10 ml volumetric flasks that had been assayed for total activity in a 4-pi gamma ionization chamber of known efficiency.* To determine the efficiency of the scintillator counter response for increasing volumes, the small aliquots were successively diluted with weak acid to yield the results shown by Figure 3. These curves served as a basis for conversion of observed counting rates of each plant sample to disintegration rates according to the following procedures:

1. After compressing with the punch and die the volume of the dry plant material in the counting tube was estimated by comparing it with an identical 100 ml tube which was calibrated in cubic centimeters.

* The 4-pi gamma ionization chamber is an argon filled (600 psig at 70°F) steel ionization chamber 11 inches in diameter by 14 inches high, shielded with 3 inches of lead. The ionization current produced in the chamber is read out on a microammeter. The useful ionization current output ranges between 4×10^{-10} and 3×10^{-5} milliamps (ma). Readings are normalized to a standard response of 5.60×10^{-7} ma for 100 micrograms of radium. The response of the 4-pi ionization chamber to many radioisotopes has been determined.¹⁷

FIGURE 3 VARIATION OF SCINTILLATION COUNTER RESPONSE WITH TOTAL SOLUTION VOLUME (NALGENE TEST TUBES)

2. The sample was counted for gross activity after which its counting rate was corrected for background* and normalized to a Cs-137 standard.
3. The net corrected count rate was then converted to disintegration rate from using the appropriate curve of Figure 3.

* Samples were counted for at least one minute or until the accumulated counts were at least five times the background counts per minute.

RESULTS

Plant Uptake Contamination Factors

A plant uptake contamination factor (a_{SU}) is defined as the concentration of a radionuclide in a plant part (atoms per gram of dry plant part) divided by the concentration of the same radionuclide in the soil (atoms per gram of dry soil). It will be noted that:

$$a_{SU} = \frac{\text{atoms/gm of dry plant}}{\text{atoms/gm of soil}} = \frac{\text{d/s/gm of dry plant}}{\text{d/s/gm of soil}}$$

Disintegration rates, decay corrected to planting date, were used to calculate the a_{SU} values reported herein.

Appendix A presents a summary sheet for each soil container. Information in each summary sheet includes: (1) plant age in days from date of planting, (2) number of plants harvested, (3) dry weight in grams per plant, (4) dry weight (grams) of counting sample, (5) specific activity of the sample in disintegrations per second per gram (d/s/gm), and (6) uptake contamination factors (a_{SU}) for each sample harvested. Specific activity of the soil, date of planting, and plant emergence date are also listed.

Computed Values of a_{SU} at Crop Maturity

Average a_{SU} values for each crop at maturity are summarized in Tables 15 through 17. These values were obtained for plants at final harvest when the edible portion had matured to a marketable stage.

The a_{SU} values listed in Table 17 for Ce-144 and Ru-106 plant-soil combinations, however, should be treated at a low confidence level. The

* Average of all boxes at final harvest.

Ru-106 and Ce-144 soil containers were those utilized in the 1965 plant uptake experiments,⁸ and the soil activity had decayed to a level which was too low to provide adequate gamma counting rates in the harvested plant samples. The computed values for Ru-106 and Ce-144 will be used only for general comparisons.

Comparisons of a_{SU} values derived for various plant part-soil radionuclide combinations at crop maturity are given in Tables 18 and 19. In Table 18, a_{SU} values for radionuclides are compared for each plant part for crops grown in Oakley Sandy Loam, and in Table 19, a_{SU} values are compared for each radionuclide-soil combination.

Table 18 shows that a_{SU} values for Sr-85 are the highest in all instances, usually by an order of magnitude. This is in agreement with the results obtained in the 1965 plant uptake experiments.⁸ In tomato and corn samples, Cs-137 is found to be the next in order of importance. In wheat and potato samples, Cs-137 and Ru-106 are found to be next in order of importance, with Ru-106 higher in wheat samples, and Cs-137 higher in potato samples. Ce-144 is generally found to be the least important in all plant samples.

Table 19 shows that a_{SU} values for the edible portion of each plant was the lowest in all cases except for tomato samples, where Cs-137 a_{SU} values in the harvested fruit were not significantly lower than other portions of the plant. The leafy portion of all plants usually had the highest a_{SU} values.

Dependence of a_{SU} on Exchangeable Soil Cations

The relationship between a_{SU} and relative cation ionic or available concentration was discussed earlier and an equation was proposed which

relates the uptake factor to the available cation concentration; for example, calcium, according to $a_{SU} = a_{SU}^0 [Ca^{++}]^{-m}$ where a_{SU}^0 and m are empirical constants and $[Ca^{++}]$ is the available calcium concentration in milligrams of calcium per gram of soil. An approximate measure of the latter is provided by the soil analysis data for total chemically extractable calcium (exchangeable plus soluble). As noted in Table 4, however, the soluble calcium values are relatively low with respect to the exchangeable concentrations, and the latter values were taken as representative of the total soil available calcium for determination of the equation constants.

Using the data measured for mature samples, the equation constants were determined by least square fits to plots of a_{SU} versus exchangeable calcium for the crops and soils employed in the present studies. The results are summarized in Table 20 and are compared where possible with values from earlier experiments. In general, the agreement is only fair, but probably consistent with the limited number of experiments and test soils.

As in the previous work, only a limited number of soils were employed and the derived constants are based at most on no more than three to four values for exchangeable calcium in the native soils. In a few cases, however, the experiments were repeated for a given crop-radionuclide combination on additional soils. An example is illustrated in Figure 4 for wheat and radiostrontium. In this figure the combined data are shown for the last two experiments. The similarity in slopes for the three plant parts is evident readily as is the order of a_{SU} values ranging from the lower values for the grain to the higher values in the leaves. The similarity in slopes appears to be reasonable, since it would be expected that lower available strontium to the root system (at higher soil calcium levels) would equally affect all plant parts. Further experiments would

FIGURE 4 VARIATION OF a_{SU} FOR SR-85 WITH EXCHANGEABLE CALCIUM, WHEAT - GRAIN, LEAVES AND STALKS

be required to confirm this observation and to provide improved confidence in the desired value for the slope.

The effect of added calcium on a_{SU} values for radiostrontium was determined for all crops grown in Hanford sandy clay loam soils. Calcium in the form of hydrous calcium sulfate was added to the as-received loam in amounts of 290, 580, 1158, and 1738 grams of gypsum, or 50, 100, 200, and 300 percent of the total exchangeable calcium level. Four boxes were prepared for each level and planted with tomatoes, potatoes, wheat, and corn. The resulting a_{SU} values for these crops grown in the amended loam soils are given in Table 21.

The a_{SU} values for all crops grown with a 50 percent amendment, as compared to the values with no additional calcium, showed a decrease in a_{SU} in all cases, with the largest change noted for wheat leaves and the smallest for corn kernels. In all cases the smallest variation was found in the edible portion. These findings agree with those reported in References 7 and 8. The a_{SU} values obtained with 100 percent calcium addition showed a decrease in a_{SU} from the 50 percent amendment in only 42 percent of the samples, while the subsequent calcium additions of 200 and 300 percent showed no significant decrease over those obtained with the initial 50 percent amendment.

Comparison of Soil Container and Field Experiments

The measured a_{SU} values for samples grown in fields at Camp Parks and at Hanford are summarized in Table 22 along with the corresponding values for crops grown in soil containers. The paired values for each plant part have been plotted in Figure 5 in which the 45° line represents equal values.

Both crops grown in the Hanford soil, tomatoes and wheat, show reasonably good agreement between container and field data with a slight bias

FIGURE 5 COMPARISON OF RADIOSTRONTIUM a_{SU} VALUES FOR SAMPLES GROWN IN SOIL CONTAINERS AND IN THE FIELD

in favor of higher a_{SU} values indicated for wheat samples grown in the field. An opposite effect is shown for the wheat crop grown in Camp Parks clay, which gave the largest variation between the containers and the field. On the average, the container a_{SU} values for Camp Parks wheat were slightly more than three times higher than the field samples. For all of the paired values taken as a whole, eight values were higher in crops grown in the soil containers and six were higher in the field samples. The average ratio of high to low value was 2.8 for the former and 1.8 for the pairs which gave higher field values.

The purpose of these experiments was to test the hypothesis that the large soil containers used in this work provide realistic simulation of an actual field environment. These rather limited experiments clearly do not verify the hypothesis for general application. On the other hand, neither do they disprove it. In fact, the agreement appears to be adequate to support the continuing application of the soil container data to post-attack predictions of food contamination,* at least in the absence of additional experimental work.

As part of the field experiments a limited number of additional tests were undertaken to derive information relating to several experimental variables. These included comparisons of a_{SU} values measured for various methods of application of the synthetic particle fallout, seeded (first crop) wheat with volunteer (second crop) wheat, and synthetic

* These considerations apply to the early postattack period when the uptake route is relatively less important than other sources of contamination. The uncertainties reflected in the data would undoubtedly assume increasing importance for purposes of assessing the longer-term hazard, or for evaluating uptake of world-wide fallout.

particle fallout with solution simulant. The results are presented, respectively, in Tables 23 through 25. In nearly every case the agreement appears to be well within the experimental uncertainty and indicates no appreciable difference in the results by the various methods. A possible exception is the higher a_{SU} values for the first wheat crop at Reedley (Table 24), which may be related to a relatively poor crop yield as compared to the volunteer wheat crop yield. The latter winter crop received additional rainfall which allowed for a normal root penetration.

The good agreement between the particle and solution simulant results supports the previously unproven contention that little difference is to be expected between the two methods of application, at least for this type of study and radionuclide-soil combination. From an experimental point of view, however, the particle type of fallout provides a considerably more convenient vehicle than a solution form for application to field plots, and in any event simulates more realistically the physical mixing of soil and fallout particles. For certain types of soils such mixing may have an important influence on the uptake process.

Effect of Heat Treatment on Observed Uptake

In the previous experiments a limited number of tests were undertaken in which samples of synthetic fallout were subjected to successively higher temperatures prior to mixing with the soil. The results indicated a marked decrease in the available radionuclide with corresponding lower a_{SU} values, by as much as a factor of ten or more. The experiments were repeated more extensively in the present work with the results shown in Table 26. Also shown is the solubility of the radiostrontium used, as measured in water and 0.1 N HCl. In general, and as expected, the decrease in a_{SU} for the heated simulant corresponds more closely to the decreased solubility in water.

Sr-85	percent soluble in water	86.6%	1.4%	1.4%	1.5%
Sr-85	percent soluble in 0.1 N HCl	99.4	75.9	17.4	13.1

Although the present studies were conducted only with radiostrontium, laboratory work^{10,11,12} with additional radionuclides provides evidence that similar decreases would be expected. These results are significant with respect to expected levels of radionuclides in crops, for a given level of fallout contamination, and clearly indicate the necessity for specifying the degree of availability of radionuclides for a given type of fallout.

CONCLUSIONS

The uptake of four radionuclides (Sr-85, Ru-106, Cs-137, and Ce-144) was measured for four plants (wheat, tomatoes, corn and potatoes) grown in four different soil types (sandy loam, sandy clay loam, silty clay and clay). Plants were grown in large soil containers that allowed most of the root system to develop under normal field conditions. Sampling started as soon as the plants sprouted and continued at frequent intervals depending on growth characteristics of the plant. Plant uptake contamination factors (a_{SU}) were calculated for each of the samples harvested. Comparisons of the uptake for various plant part-soil-radionuclide combinations at crop maturity show that the a_{SU} values for Sr-85 are the largest in all instances, usually by an order of magnitude. The a_{SU} values for Cs-137, Ru-106, Zr-Nb-95, and Ce-144 show no consistent pattern and are randomly distributed high and low among the plant part-soil combinations. The a_{SU} values for the edible portion of each plant were lowest in every case, and usually the leafy portion of the plants had the largest a_{SU} value. These general observations support and extend the results of previous experiments.

Only limited data were available for evaluating the effects of available calcium on radionuclide uptake but, taken with the results of previous work, supported the postulated decrease in uptake in a manner approximately inversely proportional to the exchangeable calcium concentration in the soil. These results again emphasized the generally lower uptake values observed in the work as compared to literature values. The lower values in these experiments have been attributed to the growing of crops in large containers, as opposed to values based on literature

data which are reported for experiments using small pot containers. The large soil containers allowed the plant root systems to develop in a manner more nearly approximating field conditions.

To test this assumption further some field studies were conducted in which crops were grown on small test plots at two different field locations. The data were not extensive enough to confirm the validity of the large container approach but were in sufficiently good agreement to support the continuing application of the large container data to estimations of early postattack period food contamination levels. As part of the field studies, a limited number of additional experiments were conducted to compare measured a_{SU} values for various methods of mixing the contaminant with the soil and also to compare the results obtained by applying the contaminant in normal particle form and also as a solution. In all cases no significant differences were found.

By far the largest changes in a_{SU} values were produced when the availability of the radionuclides for uptake was reduced by thermal pre-treatment of the fallout simulant. The results verified the previous reductions in a_{SU} values for wheat by as much as a factor of 10. In the present work the observations were extended to include the three additional crops of tomatoes, corn and potatoes and similar reductions in a_{SU} values were found.

Recommendations

In view of the generally low uptake values observed in this and previous work it appears very likely that relatively little postattack hazard to humans can be anticipated from the consumption of foods grown in soils which have been contaminated up to the levels employed in these experiments. The primary contribution of the current series of experiments has been to significantly extend the amount of available data for

analyses of postattack food supply problems. It is recommended that the data be included in subsequent analytical studies directed to evaluations of human survival following nuclear attack.

Possibly the most serious problem encountered in the conduct of the work has been associated with the difficulty in attempting to generalize the results. Although the number of radionuclides and crops studied are probably adequate to cover a wide range of postattack situations, the work has of necessity been restricted to only a limited number of soil types. Although undertaking additional work would clearly be dependent on research priorities, it is recommended that any additional studies be specifically oriented toward an emphasis on soil variables.

STANFORD RESEARCH INSTITUTE, Menlo Park, California

EXPERIMENTAL INVESTIGATION OF PLANT UPTAKE CONTAMINATION FACTORS,

by James D. Sartor, Pamela G. Kruzic, William B. Lane, and
James L. Mackin, 167 pp, September 1968, UNCLASSIFIED

SRI Project No. MU-6502, Contract No. N00228-67-C-2036, OCD Work
Unit No. 3143B

The uptake of four radionuclides (Sr-85, Ru-106, Cs-137, and Ce-144) was measured for four plants (wheat, tomatoes, corn and potatoes) grown in four different soil types (sandy loam, sandy clay loam, silty clay and clay). Plants were grown in large soil containers that allowed most of the root system to develop under normal field conditions. Plant uptake contamination factors (a_{su}) were calculated for each sample harvested. Comparisons of the uptake for various plant part-soil-radionuclide combinations at crop maturity showed that the a_{su} values for Sr-85 were the largest in all instances, usually by an order of magnitude. The a_{su} values for the edible portion of each plant were lowest in every case, and usually the leafy portions of the plants had the largest a_{su} value.

SRI Project No. MU-6502, Contract No. N00228-67-C-2036, OCD Work
Unit No. 3143B

The uptake of four radionuclides (Sr-85, Ru-106, Cs-137, and Ce-144) was measured for four plants (wheat, tomatoes, corn and potatoes) grown in four different soil types (sandy loam, sandy clay loam, silty clay and clay). Plants were grown in large soil containers that allowed most of the root system to develop under normal field conditions. Plant uptake contamination factors (a_{su}) were calculated for each sample harvested. Comparisons of the uptake for various plant part-soil-radionuclide combinations at crop maturity showed that the a_{su} values for Sr-85 were the largest in all instances, usually by an order of magnitude. The a_{su} values for the edible portion of each plant were lowest in every case, and usually the leafy portions of the plants had the largest a_{su} value.

DETACHABLE SUMMARY

This report describes the results of experiments conducted for the purposes of evaluating the uptake of selected fission product radio-nuclides through their root systems, and for evaluating the dependence of the contamination factors on such parameters as plant type, soil type, plant age, soil nutrients, and fallout solubility. It was also necessary to correlate the measured plant uptake contamination factors with soil characteristics for subsequent application in mathematical root uptake contamination models.

The approach taken followed earlier work in which plants were grown in large containers under conditions designed to reproduce, as closely as possible, the growth of food crops under actual field conditions. In addition, during the current work, a limited number of field tests were conducted to test the hypothesis that the large containers used provided a realistic simulation of an actual environment. Primary consideration was given to the study of radiostrontium with crops also grown in Cs-137, Ru-106 and Ce-144 soil containers which were available from previous experiments. The farmland plots were contaminated only with radiostrontium.

Test soils included sand, loam and clay soils from previous work and two additional soils representing widely distributed California agricultural soils. The crops studied were wheat, tomatoes, corn and potatoes.

Sampling started as soon as the plants sprouted and continued at frequent intervals depending on growth characteristics of the plant. Plant uptake contamination factors (a_{SU}) were calculated for each of the samples harvested. Comparisons of the uptake for various plant part-soil-radionuclide combinations at crop maturity showed that the a_{SU} values for Sr-85 were the largest in all instances, usually by an order of magnitude. The a_{SU} values for Cs-137, Ru-106, and Ce-144 showed no consistent pattern and were distributed randomly high and low among the plant part-soil combinations. The a_{SU} values for the edible portion of each plant were lowest in every case, and usually the leafy portion of the plants had the largest a_{SU} value. These general observations support and extend the results of previous experiments.

Only limited data were available for evaluating the effects of available calcium on radionuclide uptake but, taken with the results of previous work, supported the postulated decrease in uptake in a manner approximately inversely proportional to the exchangeable calcium concentration in the soil. These results again emphasized the generally lower uptake values observed in the work as compared to literature values. The lower values in these experiments have been attributed to the growing of crops in large containers, as opposed to values based on literature data which are reported for experiments using small pot containers. The large soil containers allowed the plant root systems to develop in a manner closer to field conditions.

To test this assumption further some field studies were conducted in which crops were grown on small test plots at two different field locations. The data were not extensive enough to confirm the validity of the large

container approach but were in sufficiently good agreement to support the continuing application of the large container data to estimations of postattack food contamination levels. As part of the field studies, a limited number of additional experiments were conducted to compare measured a_{SU} values for various methods of mixing the contaminant with the soil and also to compare the results obtained by applying the contaminant in normal particle form and also as a solution. In all cases no significant differences were found.

By far the largest changes in a_{SU} values were produced when the availability of the radionuclides for uptake was reduced by thermal pretreatment of the fallout simulant. The results verified the previous reductions in a_{SU} values for wheat by as much as a factor of 10. In the present work the observations were extended to include the three additional crops of tomatoes, corn and potatoes and similar reductions in a_{SU} values were found.
